Background: There is a low utilization rate of donated donor lungs. Historically, transplantation of lungs from hepatitis C-viremic donors to hepatitis C (HCV) negative recipients was avoided due to concern for worse graft survival. In the past few years with the advent of direct acting antiviral (DAA) therapy, there are emerging data suggesting the safety and efficacy of transplanting thoracic organs from HCV-viremic donors. This study assessed the differences in donor characteristics and allograft-specific clinical features at the time of organ offer and investigated whether these variables differed in HCV-viremic versus HCV-negative donors and impacted recipient outcomes.

Methods: We conducted a single-center, retrospective cohort study of adult patients who underwent a lung transplant at Brigham and Women's Hospital between March 2017 and October 2018. Patients were stratified based on their donor HCV status (HCV-viremic versus HCV-negative). Donor and allograft-specific characteristics and clinical features including chest imaging and bronchoscopy reports, respiratory cultures, and the donor's oxygenation as measured by the arterial partial pressure of oxygen (PaO₂) were collected as well as recipient baseline characteristics and transplant outcomes.

Results: During the study period, 42 and 57 lung transplants were performed from HCV-viremic and HCV-negative donors, respectively. Donor age was similar in both cohorts. More HCV-viremic donors died from drug intoxication (71% versus 19%, P=0.0001) and had a history of cigarette use (83% versus 5%, P=0.0001) and drug use (76% versus 49%, P=0.007). There were differences in the baseline recipient characteristics including a lower median lung allocation score in the HCV-viremic cohort. The organ-specific clinical characteristics including the terminal PaO₂, chest imaging and bronchoscopy findings, and evidence of pulmonary infection were similar between the two cohorts. The recipient outcomes overall were excellent and did not differ significantly in both cohorts in terms of graft and patient survival at 6 and 12 months.

Conclusions: Despite a greater proportion of HCV-viremic donors being increased risk with a history of drug and cigarette use and having died as a result of drug intoxication, the quality of the HCV-viremic donor organs did not differ from the HCV-negative donor organs or impact graft and recipient survival. Due to an increasing number of transplants from increased risk donors and in order to develop safe and effective protocols to perform lung transplants from HCV-infected donors, further characterization of the donor and allograft-specific clinical features and longer-term recipient outcomes is greatly needed.

Introduction

The number of patients with end-stage lung disease who are on the lung transplant waitlist continues to outpace the number of lung transplants performed annually. This imbalance leads to a high mortality on the waitlist. In the United States in 2017, 326 patients with end-stage lung disease died while on the waitlist or were removed from the waitlist due to becoming too sick to undergo transplantation (1). Fortunately lung transplant rates in the US have increased annually from 106.6 per 100 waitlist-years in 2012 to 173.2 per 100 waitlist-years in 2017 (1). This is largely due to having more deceased donors, but also reflects an increase in the number of donor organs used that are recovered. However, lung donor utilization rates remain the lowest of all donor solid organs (2). Strategies are being developed to enable the successful transplantation of deceased-donor organs that historically were discarded due to donor risk factors such as older age, cardiac death, known infections, or behaviors that increase the risk of transmission of infections such as hepatitis C (HCV), hepatitis B, or human immunodeficiency virus (3).

Thoracic organ donors with active HCV were previously declined due to the high risk of HCV transmission and the development of HCV-related complications in the recipient, as well as concerns of poorer post-transplantation outcomes with lower patient and graft survival (4-7). These concerns are being re-evaluated in the era of direct acting antivirals (DAA). DAA have HCV cure rates greater than 97%, are well tolerated, and have limited drug interactions. In the past few years, there are emerging data from single center studies showing the safety and efficacy of transplanting lungs from HCV-infected donors into HCV-uninfected recipients (8). The DONATE HCV Trial reported 44 patients who underwent thoracic organ transplantation at our transplant center (36 lungs and 8 hearts) from HCV viremic donors and were treated with a shortened, four-week course of a pangenotypic DAA, sofosbuvir/velpatasvir, that was initiated a few hours after transplant (9). Of the 35 patients with six months of follow-up at the time of publication, all participants achieved the primary endpoint of sustained virologic response 12 weeks after treatment completion (SVR12) and 6-month graft survival. The recipient outcomes were similar between those who had received organs from HCV-infected donors and HCV-uninfected donors. However, the odds of having acute cellular rejection requiring treatment in the HCV-infected lung cohort were larger than that of the HCV-

negative lung cohort.

Mehra and colleagues showed that lung allograft survival does not differ significantly between donors who died from drug intoxication and those who died from other causes (10). Two single center studies have shown that short-term lung allograft outcomes are similar between HCV-infected donors and HCV-uninfected donors (9,11). However, these studies have not assessed whether characteristics of the donor lung allograft at the time of organ offer, including specific patient and organ-related risk factors, differ between HCV-infected and HCV-uninfected donors and impact post-transplantation outcomes.

The objectives of this retrospective study were to: (I) evaluate the baseline donor demographics, clinical risk factors, and allograft-related clinical features including pulmonary function, infection, and chest imaging and bronchoscopy findings between the HCV-viremic donors and HCV-uninfected donors; (II) assess the recipient baseline demographics and clinical risk factors; and (III) analyze the potential impact of these patient specific and organ specific characteristics on post-transplantation clinical outcomes between the two cohorts.

Methods

Patient population and study design

This is a retrospective cohort study that includes adult patients with end-stage lung disease who underwent a single or bilateral lung transplant at Brigham and Women's Hospital between March 1, 2017 and October 31, 2018 and their corresponding organ donors. Patients were stratified based on their donor HCV status at the time of organ procurement: active HCV infection [HCV nucleic acid amplification test (NAT) positive] or HCV negative [HCV NAT and antibody (Ab) negative]. Recipients of donor lungs who had evidence of prior, resolved HCV infection (HCV Ab positive but NAT negative) were excluded from this analysis.

The transplant recipients of HCV-viremic donor lungs had been enrolled in the DONATE HCV Trial (NCT03086044). Donor acceptance criteria for quality and procurement protocols were the same for HCV NAT positive donors as for HCV-negative donors. HCV-viremic donors were accepted before knowing the HCV genotype and quantitative HCV viral load. Recipients of lungs from HCV-viremic donors received a shortened, pre-emptive four-week regimen of DAA treatment with sofosbuvir

(400 mg)/velpatasvir (100 mg), once daily, beginning a few hours post-transplantation. All recipients had an undetectable HCV viral load prior to two weeks and achieved SVR12. Additional details of the DONATE HCV Trial, including the trial protocol, inclusion and exclusion criteria, trial oversight, and initial findings can be found in the 2019 manuscript by Woolley *et al.* and in the accompanying online Supplementary Appendix (9). This study was approved by our center's Institutional Review Board and was conducted in collaboration with New England Donor Services.

Data collection

Characteristics of the donor lung allograft at the time of organ offer, including specific patient and organ-related risk factors, were obtained from the United Network for Organ Sharing (UNOS) Standard Transplant Analysis and Research (STAR) database and UNOS DonorNet. The donor arterial partial pressure of oxygen (PaO₂) on 100% fraction of inspired oxygen (FiO₂) and positive end expiratory pressure (PEEP) 5 cm of water is considered a critical measure of post-transplant allograft function and was assessed for each cohort. Additional allograft clinical features including chest imaging and bronchoscopy findings as well as respiratory cultures were collected. The report of the last chest radiograph and chest computed tomography (CT) study that was available in the DonorNet chart was reviewed for each donor. Findings of significant atelectasis, infiltrates, consolidations, effusions greater than “small” or “trace”, and pneumothoraces were deemed abnormal. CT scans with findings limited to bibasilar atelectasis were considered normal. The donor bronchoscopy reports were reviewed and evidence of purulent or bloody secretions, signs of aspiration or foreign body, and aberrant anatomy were deemed abnormal. Respiratory cultures from the donor hospitals were reviewed and considered positive if pathogens that are not considered normal oral flora grew. Whether the donor was considered to have had a pulmonary infection was a designation made by the donor hospital and was obtained from the UNOS STAR file.

We assessed the medical records of the transplant recipients who underwent a lung transplant during this 20-month period and obtained baseline demographics, clinical data, and transplant outcomes of these patients from our prospectively-maintained DONATE HCV database including length of index hospitalization, readmissions, episodes of acute cellular rejection requiring treatment, graft survival, and patient survival. The lung allocation

score is a numerical value from 0 to 100 utilized by UNOS to prioritize lung transplants in the United States based upon highest value. The lung transplant recipients included in this analysis had at least six months of follow-up data.

Statistical analysis

Basic clinical and sociodemographic characteristics were captured descriptively. Continuous variables were summarized with means and standard deviations or medians and ranges or interquartile ranges (IQR). Categorical data were summarized with counts and percentages. We compared sociodemographic and clinical characteristics between the HCV-viremic and HCV-negative cohorts using the Wilcoxon rank-sum test, Student's *t*-test, and Fisher exact tests. Statistical analyses were performed using Stata SE 15 version 15.1 (StataCorp LLC, College Station, Texas, USA).

Results

Study cohort

Between March 1, 2017 and October 31, 2018, there were 99 lung transplants performed from either a HCV-viremic donor (n=42) or from a HCV-negative donor (n=57). All 99 patients included in this study had at least 6 months of follow-up and 28 out of 42 (67%) recipients in the HCV-viremic cohort and 49 out of 57 (86%) recipients in HCV-negative cohort had 12-months or more of follow-up time. Baseline donor and recipient sociodemographic and clinical data for the two cohorts are presented in *Table 1*. Donor age was similar in the two cohorts. The donor cause of death was more often due to anoxia in the HCV-viremic cohort (79% versus 42%, P=0.0001), while more HCV-negative donors died from head trauma (39% versus 14%, P=0.012). The mechanism of the donor's death, a separate UNOS classification, was more often drug intoxication in the HCV-viremic cohort (71% versus 19%, P=0.0001). Additionally, more HCV-viremic donors had a prior history of cigarette use (83% versus 5%, P=0.0001), illicit drug use within 6 months of death (76% versus 49%, P=0.007), and were considered at increased risk for transmission of human immunodeficiency virus, hepatitis B virus, or HCV as defined by the U.S. Public Health Service (100% versus 21%, P=0.0001) as compared to the HCV-negative cohort.

The age of the recipients was similar in the two cohorts and the majority of recipients in both cohorts underwent a bilateral lung transplant. The median lung allocation score was lower in the HCV-viremic cohort (33.17 versus 38.74,

Table 1 Baseline characteristics of the transplant donors and recipients

Characteristic	HCV-NAT+ (n=42)	HCV-negative (n=57)	P value
Donor			
Median age, years [range]	34 [21–57]	35 [14–64]	0.42
Male, n [%]	22 [52]	38 [67]	0.21
Cause of death, n [%]			
Anoxia	33 [79]	24 [42]	0.0001
Head trauma	6 [14]	22 [39]	0.012
Cerebrovascular/stroke	3 [7]	10 [17]	0.23
Other	0	1 [2]	1.00
Mechanism of death, n [%]			
Drug intoxication	30 [71]	11 [19]	0.0001
History of cigarette use, n [%]	35 [83]	3 [5]	0.0001
Illicit drug use within 6 months of death, n [%]	32 [76]	28 [49]	0.007
Increased risk status, n [%] [†]	42 [100]	12 [21]	0.0001
Recipient			
Median age, years [range]	61 [36–71]	63 [28–73]	0.60
Male, n [%]	17 [40]	34 [60]	0.07
Caucasian, n [%]	38 [90]	52 [91]	0.37
Median lung allocation score (IQR)	33.17 [32.80–35.34]	38.74 [35.05–47.83]	0.00001
Underlying disease, n [%]			
Restrictive lung disease	12 [29]	40 [70]	0.0001
Obstructive lung disease	25 [59]	8 [14]	0.0001
Cystic fibrosis	4 [10]	7 [12]	0.76
Pulmonary vascular disease	1 [2]	2 [4]	1.00
Bilateral transplant, n [%]	41 [98]	51 [89]	0.23

Data are presented as median [range], or number [percentage]. Analyses are not adjusted for multiple comparisons. [†], Per the U.S. Public Health Service, an increased-risk donor has baseline characteristics that may increase the risk of disease transmission (HIV, HBV, and HCV) to a potential transplant recipient. A P value less than 0.05 was deemed statistically significant. IQR, interquartile range; HCV, hepatitis C virus; NAT, nucleic acid amplification test.

P=0.00001) and a greater proportion of recipients in the HCV-viremic cohort had obstructive lung disease (59% versus 14%, P=0.0001). More recipients in the HCV-negative cohort had restrictive lung disease (70% versus 29%, P=0.0001).

Donor lung allograft-specific clinical features

Overall, the organ-specific clinical characteristics and findings were similar between the HCV-viremic and HCV-

negative donors (Table 2). The donor median terminal PaO₂ on 100% FiO₂ and PEEP 5 cm of water was greater than 400 mmHg and similar in both cohorts as was the mean number of days the donor had been on the ventilator. Analyses of the chest imaging findings revealed that the majority of chest radiograph and CT studies were abnormal and there were no significant differences between the two cohorts. Moreover, the specific abnormalities appreciated on chest CT were equally distributed between the groups.

Table 2 Lung allograft-specific clinical features and diagnostic data used for donor evaluation

Donor evaluation	HCV-NAT+ (n=42)	HCV-negative (n=57)	P value
Median terminal PaO ₂ :FiO ₂ , mmHg [IQR]	433 [360–495]	416.5 [352–455]	0.35
Mean days on ventilator, ± SD	3.9±2.2	3.8±2.4	0.83
Chest radiograph, n*	42	57	
Abnormal, n [%]	31 [74]	48 [84]	0.22
Chest CT scan, n*	36	57	
Abnormal, n [%]	31 [86]	48 [84]	1.00
Consolidation: bilateral	22 [71]	32 [67]	0.67
Consolidation: unilateral	6 [19]	3 [6]	0.084
Pleural effusion	2 [6]	5 [10]	0.70
Pneumothorax	1 [3]	4 [8]	0.65
Bronchoscopy, n*	42	54	
Abnormal, n [%]	13 [31]	24 [44]	0.21
Respiratory culture, n*	34	51	
Positive, n [%]	28 [82]	35 [69]	0.21
Staphylococcus species [‡]	14 [50]	11 [31]	0.088
Streptococcus species	1 [4]	3 [9]	0.35
Gram negative species	2 [7]	4 [11]	1.00
Candida species	2 [7]	6 [17]	0.47
Polymicrobial	9 [32]	11 [31]	0.78
Pulmonary infection, as reported by donor hospital, n [%]	34 [81]	48 [84]	0.79

Data are presented as median [range], mean ± SD (standard deviation), or number [percentage]. Analyses are not adjusted for multiple comparisons. n*, number of results available for review; †, 100% and 91% were *Staphylococcus aureus*, respectively. A P value less than 0.05 was deemed statistically significant.

Having a bilateral consolidation was the most commonly appreciated finding in both cohorts. The percentage of bronchoscopy reports with abnormal findings was also similar between the two cohorts. The majority of donors in both cohorts were reported to have had a pulmonary infection and had positive respiratory cultures that were obtained at the donor hospital, of which more than half were *Staphylococcus aureus* in the HCV-viremic cohort compared to 31% in the HCV-negative cohort.

Transplant recipient outcomes

The recipient outcomes overall were excellent in both cohorts in terms of graft and patient survival at both 6 and 12 months (Table 3). Despite the HCV-viremic cohort

having a longer mean donor ischemic time, there were no transplant recipients in the HCV-viremic cohort who had grade 3 pulmonary graft dysfunction at 72 hours. Lung transplant recipients of HCV-negative donors had a significantly longer mean length of hospitalization (12 versus 6 days, P=0.011) as well as a longer mean intensive care unit stay (23 versus 16 days, P=0.019). The odds of having acute cellular rejection requiring treatment were larger in the HCV-viremic cohort at both 6 and 12 months. This finding was not significant and was lower when adjusted for pertinent donor and recipient baseline characteristics in a logistic regression (including the lung allocation score and underlying pulmonary disease of the recipient as well as donor ischemic time and increased risk status of the donor).

Table 3 Lung transplant recipient outcomes

Recipient outcome	HCV-NAT+ (n=42)	HCV-negative (n=57)	P value
Mean donor ischemic time, min, \pm SD	328 \pm 68	285 \pm 70	0.0028
Mean cardiopulmonary bypass time, min, \pm SD	185 \pm 36	202 \pm 62	0.13
Grade 3 pulmonary graft dysfunction at 72 hours, n [%]	0 [0]	5 [9]	0.079
Mean length of hospital stay post-transplant, days	16	23	0.019
Mean ICU stay post-transplant, days	6	12	0.011
Patients requiring rehabilitation upon discharge, n [%]	17 [40]	25 [44]	0.84
Patients with readmissions, n [%]*	30/42 [71]	47/57 [85]	0.23
Episodes of acute cellular rejection requiring treatment, n [%]			
6 months	14/42 [33]	13/57 [23]	0.26
12 months	16/28 [57]	20/49 [41]	0.24
Graft survival and patient survival			
6 months	42/42 [100]	56/57 [98]	1.00
12 months	28/28 [100]	47/49 [96]	0.53

Data are presented as mean \pm SD (standard deviation), or number [percentage]. A P value less than 0.05 was deemed statistically significant. n*, number of results available for review. IQR, interquartile range; CT, computed tomography; FiO₂, fraction of inspired oxygen; HCV, hepatitis C virus; PaO₂, partial pressure of oxygen; NAT, nucleic acid amplification test.

Discussion

The number of lung transplants performed annually is limited by a low utilization rate of donated donor lungs. Efforts to increase acceptance of donated organs include transplanting lungs from HCV-viremic donors into HCV-uninfected recipients. Due to an increasing number of transplants from increased risk donors who have died due to drug intoxication during the past few years, it is critical to understand whether differences in HCV-viremic versus HCV-negative donor and allograft-specific characteristics impact recipient and graft survival.

This study demonstrates that despite a significantly greater proportion of HCV-viremic donors having a history of cigarette use, increased risk status, and dying from anoxia in the setting of drug intoxication, the allograft-specific clinical features as assessed by the proportion of abnormal chest imaging and bronchoscopy findings, positive respiratory cultures, determination of having a pulmonary infection, and the terminal arterial partial pressure of oxygen did not differ between HCV-viremic donors and HCV-negative donors. Despite having differences in baseline demographic and clinical characteristics, the lung transplant recipients in both

cohorts had excellent graft and patient survival. Differences in the sociodemographic characteristics and clinical risk factors of the donor did not impact the quality of the allograft at the time of organ procurement or short-term post-transplantation graft and patient survival. However, though it was not statistically significant, there was an increased trend in higher rates of acute cellular rejection requiring treatment in the HCV-viremic cohort.

The evaluation of organ donors is best conceptualized as weighing a constellation of patient-specific and allograft-specific characteristics and their impact on post-transplantation allograft function and overall recipient outcomes. The findings from this study demonstrate that receiving a lung transplant from a donor who died from drug intoxication does not negatively impact graft and recipient survival and further substantiates the results from prior registry studies (10,12,13). The expanding literature supporting the utilization of these increased risk organs, however, often lacks the associated allograft-specific clinical features that are used to determine the quality of the lung itself at the time of organ procurement. The fact that the allograft-specific characteristics did not significantly differ in our study between the HCV-viremic and HCV-negative

cohorts illustrates the importance of careful assessment of the quality of the donor organ.

The increased signal of acute cellular rejection in the HCV-viremic lung transplant recipients highlights the need for longer-term follow-up to assess the potential effect of this on the incidence of chronic lung allograft dysfunction. Rejection rates were attenuated in this larger cohort compared to the findings in the initial 2019 DONATE HCV manuscript (9). Further research on the use of HCV-viremic pulmonary allografts in the era of direct-acting antiviral therapy and longer-term outcomes is important as we further expand this donor pool.

Our study is somewhat limited by its small, retrospective nature, hence, conclusions based on these data should be made with caution. Other limitations of this work include its single-center nature, the need to rely on the reports of the bronchoscopy and chest imaging findings rather than being able to review the primary data ourselves, and limited follow-up time which does not allow for the longer-term assessment of chronic lung allograft dysfunction.

These data establish that thoracic organs from HCV-viremic donors have similar organ quality and function at the time of procurement and can be transplanted safely into HCV-negative recipients, with excellent graft and patient survival at 6 and 12 months. Decisions whether to accept thoracic organs from HCV-viremic donors, increased risk donors who have died from drug intoxication, and donors with history of cigarette and drug use are complex and need to be considered in relation to the increased morbidity and mortality associated with longer waiting times on the lung transplant waitlist for alternative donor organs.
